ABSTRACT

Objective To assess whether foot and/or ankle symptoms are associated with an increased risk of worsening of knee pain and radiographic change in people with knee osteoarthritis (OA).

Methods The presence and laterality of foot/ankle symptoms were recorded at baseline in 1368 participants from the Osteoarthritis Initiative with symptomatic radiographic knee OA. Knee pain severity (measured using the Western Ontario and McMaster Universities Osteoarthritis Index pain subscale) and minimum medial tibiofemoral joint space (minJSW) width measured on x-ray were assessed yearly over the subsequent four years. Associations between foot/ankle symptoms and worsening of (i) knee pain, and (ii) both knee pain and minJSW (i.e. symptomatic radiographic knee OA) were assessed using logistic regression.

Results Foot/ankle symptoms in either foot/ankle significantly increased the odds of knee pain worsening (adjusted OR 1.54, 95% CI 1.25 to 1.91). Laterality analysis showed ipsilateral (adjusted OR 1.50, 95% CI 1.07 to 2.10), contralateral (adjusted OR 1.44, 95% CI 1.02 to 2.06) and bilateral foot/ankle symptoms (adjusted OR 1.61, 95% CI 1.22 to 2.13) were all associated with knee pain worsening in the follow up period. There was no association between foot/ankle symptoms and worsening of symptomatic radiographic knee OA.

Conclusion The presence of foot/ankle symptoms in people with symptomatic radiographic knee OA was associated with increased risk of knee pain worsening, but not worsening of symptomatic radiographic knee OA, over the subsequent four years. Future studies should investigate whether treatment of foot/ankle symptoms reduces the risk of knee pain worsening in people with knee OA.
Foot/ankle symptoms and knee OA

Key words: Knee Osteoarthritis, Arthritis, Epidemiology, Foot, Ankle, Pain
Foot/ankle symptoms and knee OA

Knee osteoarthritis (OA) is a major public health problem that causes substantial pain, physical dysfunction and impaired quality-of-life. There is no cure for knee OA and the disease often progresses to advanced stages. Although there is a discordance between knee pain and joint deterioration, both are drivers of costly joint replacement surgery. Therefore, it is important to identify risk factors that are associated with the worsening of knee symptoms, with and without concurrent structural deterioration, in an attempt to prevent disease progression.

Researchers have identified a number of risk factors for the worsening of knee OA symptoms and structure, such as age, ethnicity and malalignment, however modifiable risk factors are required to prevent progression to advanced disease and/or surgery. To date, the strongest known modifiable risk factors for worsening of knee pain in people with knee OA are a higher body mass index (BMI) and infrapatellar fat pad or intercondylar synovitis, whilst a recent meta-analysis identified greater knee pain at baseline as the only modifiable risk factor associated with structural progression. Although these risk factors are potentially modifiable, weight loss interventions have poor compliance and limited long-term success and the remaining risk factors are likely to be symptoms or sequelae of OA and thus it is unclear whether targeted treatment would slow disease progression.

A potential risk factor for worsening knee OA that has not been investigated is foot/ankle symptoms. Concurrent symptoms at the foot, ankle and knee occur more often than any other multi-joint pain presentation, and their co-occurrence substantially increases the risk of problems with walking, standing and rising from sitting compared to single- and other multi-joint symptoms. In people with knee OA, cross-sectional studies have shown that the presence of
Foot/ankle symptoms and knee OA

foot/ankle symptoms is also associated with worse knee symptoms, health-related quality-of-life, depressive symptoms and functional abilities. More recently, our longitudinal study showed that foot/ankle symptoms are an independent risk factor for developing knee OA in people free of the disease but at risk. Potential mechanisms linking foot/ankle symptoms and incident knee OA, such as foot pronation, inappropriate footwear or widespread pain, may also increase the risk for worsening in those with OA. However, as incident disease is a different phenomenon to worsening OA and risk factors may not be consistent across both, it is necessary to separately establish the association of foot/ankle symptoms with worsening OA. This is important as worse knee pain and greater radiographic severity are predictors of progression to arthroplasty.

Knowledge of risk factors in those with knee OA can provide insight into why the disease progresses in some individuals but not others and help identify potential new treatment targets for future clinical trials. Therefore, the aim of this study was to investigate whether the presence of foot/ankle symptoms at baseline is associated with an increased risk of worsening of (i) knee pain, and (ii) both knee pain and radiographic change, in people with symptomatic radiographic knee OA.

METHODS

Study population

Data were obtained from the Osteoarthritis Initiative (OAI), an online and publically available database (http://www.oai.ecsf.edu/). The OAI is a prospective multi-centre cohort study of 4796 participants aged between 45-79 years who have existing knee OA, or who are considered at-risk of the disease. The participants were recruited from four sites throughout the United States including Baltimore, Maryland; Columbus, Ohio; Pittsburgh, Pennsylvania; and Pawtucket,
Rhode Island. The institutional review board at each site approved all protocols and procedures and all participants provided informed consent. Further details regarding the wider OAI study protocols can be found online\(^1\). Our study included OAI participants with established symptomatic radiographic knee OA (n=1368), defined as both knee symptoms (pain, aching or stiffness in and around the knee on most days of the month for at least one month in the previous year\(^1\)) and radiographic evidence of knee OA (Kellgren and Lawrence [KL] grade \(\geq2\)) in at least one knee. If knee OA was present in both knees then both were included in the analyses.

**Demographic characteristics and covariates**

Demographic characteristics collected included age, sex and race (White, Black/African American or Asian/other non-white). Covariates included BMI, baseline Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain, depression measured using the Centre for Epidemiological Studies Depression Scale (CES-D)\(^1\), worst baseline KL grade, baseline minimum medial tibiofemoral joint space width (minJ SW), baseline tibial rim distance (defined as the distance between the anterior or posterior margin of the tibia, and the tibial margin of the joint space), and comorbidities assessed using the questionnaire version of the Charlson comorbidity index (CCI)\(^1\). The CCI derives a weighted score based on the presence or absence of 14 different comorbidities such as stroke, diabetes, asthma, and kidney failure, amongst others, and we dichotomised the cohort into those with ‘no comorbidities’ (CCI=0) and those with ‘one or more comorbidities’ (CCI\(\geq1\)) based on the total CCI score. Data on individual comorbidities is provided in supplementary Table 1. For descriptive purposes, we also classified participants as obese (\(>30 \text{ kg/m}^2\)), overweight (\(\geq25 \text{ and } \leq30 \text{ kg/m}^2\)) or healthy weight (\(<25\)
kg/m$^2$). Scores on the CES-D were summed and a score of $\geq 16$ was used to indicate significant depressive symptoms$^{13}$.

**Foot/ankle symptoms**

Self-reported foot/ankle symptoms were recorded for each of the left and right feet at baseline. Foot/ankle symptoms were defined as pain, aching or stiffness in the foot and/or ankle on more than half of the days during the past 30 days, consistent with previously published definitions$^{6,15}$. We classified participants as having or not having foot/ankle symptoms, as well as classifying foot/ankle symptoms as ipsilateral, contralateral or bilateral relative to the affected knee.

**Outcomes**

We investigated worsening of (i) knee pain and; (ii) both knee pain and radiographic knee OA. Knee pain severity was determined using the WOMAC pain subscale at baseline and the 12, 24, 36 and 48 month follow-up visits$^{16}$. The WOMAC pain subscale is comprised of five items and responses are recorded on a 5-point Likert scale. Scores were summed (range of 0-20) and converted to a 0-100 normalised scale, with higher scores indicating worse pain. We defined knee pain worsening as an increase of at least 9 points on the 0-100 WOMAC pain scale from baseline at any of the subsequent follow up visits, based on previously published smallest detectable difference values$^{17,18}$, and consistent with recent definitions used by others investigating risk factors for symptomatic progression in knee OA$^{19}$. People with a baseline WOMAC pain score $>91$ (and thus unable to worsen according to this definition) were excluded from these analyses.
To assess worsening of radiographic knee OA, weightbearing fixed-flexion posteroanterior radiographs of each knee were taken at baseline and at the 12, 24, 36 and 48 month visits. Radiographs were read centrally and automated software was used to identify the tibial and femoral margins of the knee joint from digitised copies of the radiographs. To determine the minJSW, the software measured the smallest distance between the tibia and the femur in the medial knee joint compartment in millimeters. Worsening of radiographic knee OA was defined as a medial tibiofemoral minJSW decrease of ≥0.7mm from baseline, based on the Osteoarthritis Research Society International and Outcome Measures in Rheumatology minimal detectable difference cut-off value. People with a baseline minJSW score of <0.7mm (and thus unable to worsen according to this definition) were also excluded from this analysis. A detailed outline of participant inclusion for each of the two aims is presented in Figure 1.

**Statistical analysis**

Descriptive characteristics of all variables at baseline were calculated according to the presence or absence of foot/ankle symptoms. Between-group differences were assessed using χ-squared tests, analysis of variance, Wilcoxon rank-sum or Kruskal-Wallis rank tests as appropriate.

To investigate whether foot/ankle symptoms were associated with worsening of knee pain (aim 1) and worsening of symptomatic radiographic knee OA (aim 2) over the subsequent four years, we used logistic regression models with the presence of foot/ankle symptoms (yes/no) as a binary explanatory variable. Models were fitted using generalized estimating equations to account for the correlation between left and right knees within participants. Models were performed unadjusted, as well as adjusted for baseline covariates determined a priori. The
Foot/ankle symptoms and knee OA

covariates included in the adjusted model for aim 1 were age, sex, BMI, WOMAC pain at baseline, race, depression, worst baseline KL grade, and Charlson Comorbidity index (dichotomised), as these factors are known to be associated with both foot/ankle symptoms and knee OA. Models for aim 2 were also adjusted for the covariates included in the model for aim 1, with baseline minJSW and baseline tibial rim distance also included.

Unadjusted and adjusted analyses were then repeated to investigate the association between ipsilateral, contralateral and bilateral foot/ankle symptoms at baseline and the worsening of knee pain and worsening of symptomatic radiographic knee OA. Logistic regression models were again fitted using generalized estimating equations to adjust for clustering of knees within participants. Significance was set at p-value ≤ 0.05 and Stata v12 (Stata Corporation, College Station, TX, USA) was used for all statistical analyses.

RESULTS

Sample characteristics

Four participants were excluded due to having a baseline WOMAC pain score of >91 in at least one knee, leaving data from 1364 participants. For aim 2, an additional 95 participants with minJSW < 0.7mm were excluded, as were 130 participants with missing minJSW, leaving 1139 participants for aim 2 analyses. People with foot/ankle symptoms were more likely to be female (p<0.001), younger (p=0.038), have a higher BMI (p=0.001) and to report more comorbidities (p=0.016), worse WOMAC knee pain score (p<0.001) and more depressive symptoms (p<0.001) at baseline than those without foot/ankle symptoms. There were no differences in race, worst KL
Foot/ankle symptoms and knee OA

grade, or minJSW at baseline between those with and without foot/ankle symptoms. Data are presented in Table 1.

Worsening of knee pain

Of the 2596 knees from 1319 participants analysed, 1,280 knees from 910 participants worsened (Table 2). See Supplementary Table 2 for the distribution of knees and participants who reported pain worsening at one time point and those who reported sustained pain worsening. The presence of symptoms in any foot/ankle at baseline was significantly associated with knee pain worsening (adjusted OR 1.54, 95% CI 1.25 to 1.91). Analyses of foot/ankle symptom laterality showed that ipsilateral (adjusted OR 1.50, 95% CI 1.07 to 2.10), contralateral (adjusted OR 1.44, 95% CI 1.02 to 2.06) and bilateral foot/ankle symptoms (adjusted OR 1.61, 95% CI 1.22 to 2.13) all significantly increased the odds for knee pain worsening in the follow up period.

Worsening of symptomatic radiographic knee OA

Of the 2005 knees from 1033 people analysed, 305 knees from 262 participants had worsening of both knee pain and minJSW (Table 3). See Supplementary Table 2 for the distribution of knees and participants who had worsening of both knee pain and minJSW at one time point and those who had sustained pain and minJSW worsening. The presence of symptoms in any foot/ankle at baseline was not significantly associated with worsening of these outcomes. Likewise, analysis based on foot/ankle symptoms laterality also revealed no significant associations between foot/ankle symptoms and worsening of both knee pain and minJSW.

DISCUSSION
Foot/ankle symptoms and knee OA

In this study, people with knee OA who also had foot/ankle symptoms were more likely to experience clinically relevant worsening of their knee pain at some time in the subsequent four years than people with knee OA but without foot/ankle symptoms. Risk for knee pain worsening increased regardless of foot/ankle symptom laterality. There were no longitudinal associations between symptoms in any foot/ankle and worsening of symptomatic radiographic knee OA.

The association between knee pain progression and foot/ankle symptoms regardless of laterality may be explained by a number of mechanisms. For example, foot pronation is associated with foot pain\textsuperscript{22}, and people with existing knee OA have been shown to walk with greater foot pronation\textsuperscript{23}, potentially to allow the foot to be plantigrade to compensate for knee varus. Thus, given that foot pronation causes greater internal tibial rotation\textsuperscript{24,25}, this may increase rotational stress on the tibiofemoral joint and peri-articular structures\textsuperscript{26}, exacerbating existing knee pain in people with knee OA. Ipsilateral and contralateral foot pronation have also been shown to increase the knee adduction moment\textsuperscript{24}, and a higher knee adduction moment is also associated with greater knee pain in people with established knee OA\textsuperscript{27}. Alternatively, associations between multiple pain locations, such as the foot and knee, may be an epiphenomenon due to an unmeasured shared risk factor such as fibromyalgia, pain catastrophizing, a multi-joint pain phenotype or generalised form of OA\textsuperscript{28}. The similar odds ratios for the association between foot/ankle symptoms on the ipsilateral and contralateral limbs, and worsening of knee pain, provide some support for this theory. Finally, certain styles of footwear, such as high heels, are associated with a greater likelihood of foot problems\textsuperscript{29} and abnormal knee biomechanics\textsuperscript{30} known to increase the risk of knee pain in older adults\textsuperscript{31}. 
Foot/ankle symptoms and knee OA

Although foot/ankle symptoms were associated with worsening of knee pain, there was no longitudinal association with worsening of both knee pain and minJSW. This may because the participants who experienced this outcome were a smaller subset (n=79) of those who had knee pain worsening, and thus the model may not have had enough power to detect a relationship. Alternatively, it is possible that our measure of radiographic progression (minJSW) recorded using x-ray was not sensitive enough to detect structural deterioration. The use of MRI measures may be more suitable to detect longitudinal joint changes not evident on x-ray. There is some support for this from a recent study that found having a greater number of painful sites (including at the foot) predicted knee cartilage loss on MRI in people aged between 50 and 80 years.

Our findings add support to the scant previous literature investigating associations between foot/ankle and knee OA symptoms. Symptoms at these two sites have previously been shown to be the most prevalent multi-joint pain pattern, and to be associated with greater functional limitations, than the co-occurrence of pain at the knee and any other joint. In a cross-sectional study using OAI data, we showed that knee OA patients with concurrent foot/ankle symptoms reported worse knee pain and other OA symptoms, in addition to worse general health and functional measures, than knee OA patients without foot/ankle symptoms. Our recent longitudinal study reported that foot/ankle symptoms are a risk factor for developing knee OA symptoms and symptomatic radiographic knee OA over the subsequent four years in people at-risk of the disease. Interestingly, this previous study found that bilateral and contralateral foot/ankle symptoms, but not ipsilateral foot/ankle symptoms, increased the risk of developing these outcomes. In contrast, we found associations between knee pain worsening and foot/ankle
Foot/ankle symptoms and knee OA

symptoms regardless of laterality in the current study. This might suggest that different mechanisms underpin the associations in incident versus worsening OA.

Some limitations may have influenced the findings of our study. Firstly, foot/ankle symptoms were self-reported and were only required to be present in the previous 30 days. Although this is consistent with the most widely used definitions of foot/ankle pain and/or symptoms\textsuperscript{15}, a clinical foot assessment or more detailed foot pain questionnaire, such as the Manchester Foot Pain and Disability Index\textsuperscript{35} (which rates a number of different aspects of foot pain and functional limitations), may have yielded different results. Secondly, participants were included based on the presence of knee symptoms, but as there was no minimum WOMAC pain score requirement in our inclusion criteria, it is possible our analyses included people who did not report any measureable knee pain. Further, knee pain worsening was only required to be present at one of the follow up visits, so our analyses included both people whose knee pain worsened temporarily at a single time-point as well as those with sustained pain worsening. Thirdly, potential mechanistic data such as foot/ankle osteoarthritis, foot posture or dynamic foot function were not recorded in the OAI dataset and therefore we were unable to include these variables in our analyses. Finally, dichotomising data such as we did with BMI and Charlson comorbidity index can also leave residual confounding\textsuperscript{36}. However when we repeated the analyses using fractional polynomials to model the continuous scores for these covariates, we found no strong evidence of this (see Table 3 in the supplementary analyses).

In summary, this study found that people with knee OA who report foot/ankle symptoms are at an increased risk of knee pain worsening compared to people without foot/ankle symptoms over
Foot/ankle symptoms and knee OA

the subsequent four years. However, foot/ankle symptoms were not associated with worsening of symptomatic radiographic knee OA. These findings are important given that knee pain worsening has been shown to be an independent predictor of future knee joint replacement surgery. Furthermore, both general and specific causes of foot pain can be treated using simple conservative interventions, suggesting foot/ankle symptoms may be a modifiable risk factor for knee OA pain worsening. Future research should investigate whether treating foot/ankle symptoms in people with knee OA reduces worsening of knee pain in this population.

</table>

OA, osteoarthritis; minJSW, minimal medial tibiofemoral joint space width; OR, odds ratios; CI, confidence intervals.
† Adjusted for age, sex, BMI, WOMAC pain at baseline, race, depression, Charlson Comorbidity index (dichotomised), worst baseline KL grade, baseline minJSW and baseline tibial rim distance.
FIGURE REFERENCES

Figure 1. Flowchart for participant inclusion and exclusion.
Osteoarthritis Initiative (OAI) participants at baseline (n=4796)

OAI participants with knee OA (n=1368)

**Aim 1**
Progression of knee pain. Eligible sample = 1364 participants (2728 knees)

*Excluded:*
- Participants who had WOMAC pain score at baseline of >91 (i.e. unable to meet outcome definition) (n=4)

**Aim 2**
Progression of knee pain and radiographic knee OA. Eligible sample = 1139 participants (2278 knees)

*Excluded:*
- Participants who had WOMAC pain score of >91 (n=4), joint space width < 0.7mm (n=95), or missing joint space width at baseline (n=130)
